A new study increases knowledge of the genetics behind aortic aneurysm, a disease that can spark life-threatening events like aortic dissections and ruptures.

University of Michigan Health-led researchers compared blood samples from more than 1,300 people who had a thoracic aortic [aneurysm](#) with more than 18,000 control samples, in partnership with U-M's Cardiovascular Health Improvement Project and its Michigan Genomics Initiative.

"After examining nearly the entire human genome for genetic changes that increase risk of aneurysm, we discovered a new change in the genetic code of a transcription factor, which means it controls many other [genes](#)," explained co-corresponding author Cristen Willer, Ph.D., a professor of cardiovascular [medicine](#), internal medicine, human genetics and computational medicine and bioinformatics at University of Michigan Health.

Then, Willer's team collaborated with Minerva Garcia-Barrio, Ph.D., an assistant professor of internal medicine, to examine the role this gene played in smooth muscle cells, a component of aorta.

"We examined this gene in human cells and discovered that the transcription factor we identified is a key factor that gives instructions to [cells](#) about when to die and replenish," said co-lead author Tanmoy Roychowdhury, Ph.D., a research fellow in the Division of Cardiovascular Medicine.

The authors say future research might investigate whether slowing down this apoptosis, or cellular death, in aortic aneurysm could reduce the risk of a person experiencing an aortic dissection or rupture in the future.
