

Booster shots offset some of omicron's immune evasion tactics

Although omicron subvariants of the SARS-CoV-2 pandemic coronavirus have evolved to evade antibody responses from the primary COVID-19 vaccine series, a new laboratory study suggests current

vaccine boosters may elicit sufficient immune protection against severe omicron-induced COVID-19 disease. The project assessed a comprehensive panel of vaccines available in the United States and around the world, as well as immunity acquired through previous infection.

The international research team was led by the lab of David Veessler, associate professor of biochemistry at the University of Washington School of Medicine in Seattle and an investigator at the Howard Hughes Medical Institute.

The findings are published as an Early Release paper Tuesday, July 19, in *Science*. The lead authors are John E. Bowen and Amin Addetia, both in the UW Medicine biochemistry department.

"The development of lifesaving vaccines is regarded as one of humanity's greatest medical and scientific achievements, which is exemplified by COVID-19 vaccines," the project team noted. The protective immunity generated by the primary vaccine series or prior infection has been severely blunted by omicron subvariants. A [booster dose](#), regardless of the type of COVID-19 vaccine, brings neutralizing antibodies against all the omicron subvariants to appreciable levels, this latest study shows

The findings come at a time when the United States government is considering recommending second boosters for adults under age 50, due to rising infection rates and the enhanced transmissibility of omicron BA.5.

This study's results are consistent with other research evidence that a third vaccine dose expands existing memory B cells in our bodies specific for the surface protein mediating entry into cells (called the spike protein) of the SARS-CoV-2 pandemic coronavirus, as well as

inducing new memory B cells. This leads to production of antibodies with enhanced potency against the omicron subvariants.

Veesler started studying coronavirus infection mechanisms and antibody counteractions years before the COVID-19 pandemic. The team on this latest project consisted of infectious disease research physicians and scientists from UW Medicine, Fred Hutch Cancer Center, and research institutes in California, Argentina, Italy, Pakistan, and Switzerland.

As the COVID-19 pandemic overstays its appearance on the world stage, genetic variants of the causative virus, SARS-CoV-2, have emerged that are more transmissible, fitter, and more adept at avoiding infection-fighting strategies. The latest variant of concern, omicron, has greatly diverged from the ancestral SARS-CoV-2 strain. It consists of several sublineages, including BA.5, which is predicted to soon dominate globally by replacing other variants.

The researchers in this week's *Science* paper first examined the functional impact of the mutations in the omicron subvariants spike proteins—the machinery on the virus that both gives it its crown-like appearance and enables it to attach to, fuse with, and infect cells. They found that the ability of the omicron BA.5 spike to bind with its host receptor (ACE2) was more than 6 times stronger than the ancestral SARS-CoV-2 strain.

In contrast, all omicron subvariants were slower at the next major step after binding with the receptor: fusing with the membrane on the host cell. The stronger binding might help the subvariants compensate for their diminished capacity to fuse with the host cells, the scientists hypothesize.

The researchers then evaluated, in human plasma samples, the neutralizing activity, elicited by vaccines or by prior infection, against

the various omicron subvariants. Some of the samples came from individuals who had COVID-19 very early on in the pandemic before vaccines were available. Only 5 of these 24 early-pandemic individuals had detectable neutralizing activity in their plasma against any of the four omicron sublineages tested. Even then, their response was very weak.

The researchers also evaluated the subvariant neutralizing antibodies elicited by vaccines produced by Moderna, Pfizer, Novavax, Janssen, AstraZeneca, Sinopharm, and Sputnik V vaccines. All vaccine primary series consisted of two doses, except for Janssen's vaccine which consisted of a single dose.

The researchers noted, "Overall, the data underscores the magnitude of evasion of polyclonal plasma neutralizing [antibody responses](#) for omicron sublineages." They added that there was "a subtle but consistently more marked effect for BA.1 and even more so for BA.4/5 compared to BA.2 and BA.2.12.1" The findings help confirm that the soon-to-be globally dominant BA.5 will be the most immune evasive SARS-CoV-2 variant to date.

Because of the rise in reinfections and breakthrough cases, public health officials in several countries recommended a booster dose several months after the initial vaccine series. Veessler and his team measured and compared the benefits of vaccine boosters on the plasma neutralizing activity against the ancestral SARS-CoV-2 virus as well as the omicron subvariants.

Based on their findings, the researchers observed, "The marked improvement in plasma neutralizing activity for subjects that received a booster dose over those that did not highlights the importance of vaccine boosters for eliciting potent neutralizing antibody responses against omicron sublineages." Thus, despite the high degree of omicron

subvariant immune escape, added booster doses with currently available vaccines will likely offer strong protection against severe disease.

Additional preliminary observations from this study suggest that the time interval between immunizations with certain available vaccines may affect the breadth and strength of the virus neutralizing responses. The researchers also think that the availability of several different vaccines might help in creating a more robust cross-reactive cellular immunity against omicron subvariants.

To be prepared for the future evolution of the ever-changing SARS-CoV-2 pandemic coronavirus, the scientists on the project stressed the importance of remaining diligent in surveillance to detect new variants. They also called for repeatedly evaluating the ongoing effectiveness of current vaccines and sustaining efforts to develop and test new vaccines and new [vaccine](#) strategies against the pandemic coronavirus and other related viruses. Those might be present in animal reservoirs and poised for causing disease outbreaks. Such efforts might lead to what the scientists describe in their paper as "stronger, longer lasting or broader protection" against the entire contingency of sarbecoviruses.
